Bayesian Spam Classification via Pólya-Gamma Data Augmentation

1. Executive Overview

Spam classification is a foundational problem in supervised machine learning, typically solved using frequentist Logistic Regression or Naive Bayes algorithms. However, in production email systems, misclassifying a legitimate email as spam (a false positive) carries a high penalty. Standard frequentist logistic regression provides point estimates, offering no native measure of uncertainty for its parameters or its final predictions.

This project implements a fully Bayesian Logistic Regression model. We compute the posterior distribution of the model weights to extract 95% credible intervals for the probability that a new email is spam. This allows automated systems to flag borderline emails for human review rather than outright deleting them when algorithmic uncertainty is high.

Because the logistic likelihood is not conjugate to any standard prior distribution, standard Gibbs sampling is mathematically impossible. To overcome this computational bottleneck, we implement Pólya-Gamma Data Augmentation. This advanced technique introduces a latent variable that renders the conditional distributions of our model Gaussian, allowing us to build an exact, highly efficient Gibbs sampler without resorting to computationally expensive Metropolis-Hastings tuning.

2. Mathematical and Statistical Framework

The Generative Model

Let $y_i \in \{0, 1\}$ be the binary indicator of whether the ith email is spam, for $i = 1, \dots, N$. Let $x_i \in \mathbb{R}^P$ be the vector of extracted features (e.g., frequency of specific spam trigger words). Let $\beta \in \mathbb{R}^P$ be the vector of regression coefficients. The likelihood of the data follows a Bernoulli distribution parameterized by the logistic link function:

$$y_i \mid x_i, \beta \sim Bernoulli(p_i) \; ; \; p_i = \frac{1}{1 + \exp(-x_i^T \beta)}$$

We assign a multivariate Gaussian prior to the weights:

$$\beta \sim Normal(b_0, B_0)$$

The Pólya-Gamma Augmentation

The posterior $p(\beta \mid y, X)$ is intractable. We can express the logistic contribution to the likelihood as an infinite mixture of Gaussian distributions by introducing a latent variable ω_i that follows a Pólya-Gamma distribution, denoted as $PG(b, c)$.

The fundamental identity is:

$$\frac{\left(\exp(\psi)\right)^a}{\left(1 + \exp(\psi)\right)^b} = 2^{-b} \exp(\kappa\psi) \int_0^\infty \exp\left(-\frac{\omega\psi^2}{2}\right) p(\, \omega \mid b, 0\,) \, d\omega$$

where $\kappa = a - b/2$. By letting $\psi = x_i^T \beta$, $a = y_i$, and $b = 1$, we introduce a local latent variable ω_i for each observation. Conditioned on ω_i, the likelihood of β becomes Gaussian, yielding two highly efficient, easily sampleable full conditional distributions:

1. Update for the latent variables (ω):

$$\omega_i \mid \beta \sim PG(1, x_i^T \beta)$$

2. Update for the coefficients (β):

$$\beta \mid y, \omega \sim Normal(m_\omega, V_\omega)$$

where the posterior variance and mean are:

$$V_\omega = (X^T \Omega X + B_0^{-1})^{-1}$$
$$m_\omega = V_\omega (X^T \kappa + B_0^{-1} b_0)$$

Here, X is the $N \times P$ design matrix, $\Omega = \mathrm{diag}(\omega_1, \ldots, \omega_N)$, and κ is an $N \times 1$ vector where $\kappa_i = y_i - 0.5$.

3. Simulated Data Generation

To validate the MCMC algorithm, we simulate a synthetic dataset of 1000 emails where the true data-generating parameters (β) are known.

```r
#### Simulated Data Generation ####

# 1. Define dimensions
N <- 1000 # Number of emails
P <- 4    # Number of features (Intercept + 3 variables)

# 2. Set the TRUE beta coefficients (Intercept, "free", "urgent", "attachment")
true_beta <- c(-1.5, 2.0, 1.2, -0.8)

# 3. Simulate feature data
X <- cbind(1, matrix(rnorm(N * (P - 1)), nrow = N, ncol = P - 1))

# 4. Calculate true probabilities and generate binary labels (0 = Ham, 1 = Spam)
psi <- X %*% true_beta
p_true <- 1 / (1 + exp(-psi))
y <- rbinom(N, size = 1, prob = p_true)
```

4. MCMC Implementation in R

We construct the Gibbs sampler using the derived full conditionals and the *pgdraw* package. The algorithm includes interim visual updates to monitor real-time chain mixing.

```r
#### MCMC Implementation in R ####
library(pgdraw)
library(MASS)
library(coda)

n_iter <- 5000
burn_in <- 1000

b_0 <- rep(0, P)
B_0 <- diag(10, P)
B_0_inv <- solve(B_0)
kappa <- y - 0.5

beta_samples <- matrix(0, nrow = n_iter, ncol = P)
beta_current <- rep(0, P)

cat("Starting MCMC...\n")
for (iter in 1:n_iter) {

  # Step 1: Sample latent variables omega_i | beta
  psi <- as.vector(X %*% beta_current)
  omega <- pgdraw(1, psi)

  # Step 2: Sample beta | y, omega
  Omega_diag <- omega
  Xt_Omega_X <- t(X) %*% sweep(X, 1, Omega_diag, "*")
  V_omega <- chol2inv(chol(Xt_Omega_X + B_0_inv))
  m_omega <- V_omega %*% (t(X) %*% kappa + B_0_inv %*% b_0)

  beta_current <- mvrnorm(1, mu = m_omega, Sigma = V_omega)
  beta_samples[iter, ] <- beta_current

  # Step 3: Interim console output for monitoring
  if (iter %% 1000 == 0) cat("Completed iteration:", iter, "\n")
}

# Discard Burn-in
posterior_beta <- beta_samples[(burn_in + 1):n_iter, ]
```

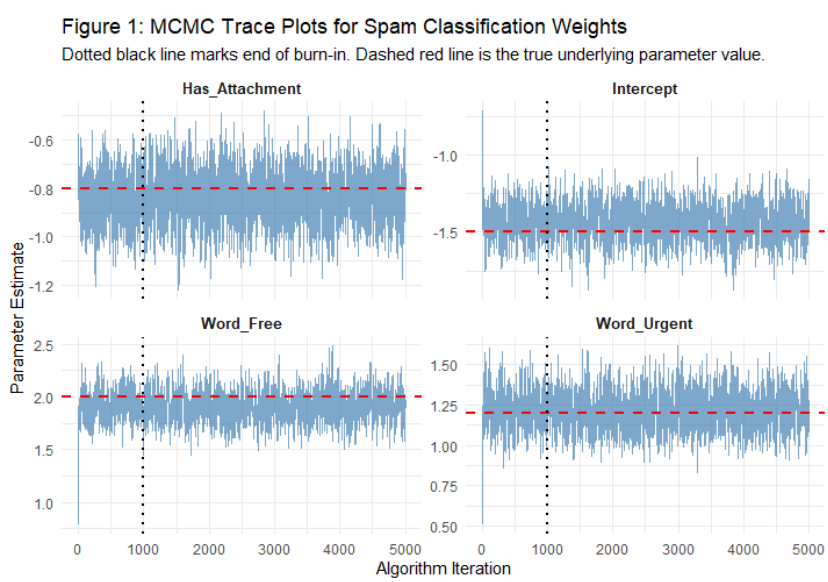

Figure 1. Interim trace plots would display the parameter chains exploring the space, converging on the true values (indicated by dashed red lines) after the burn-in period.

Figure 1 provides visual confirmation of the Gibbs sampler's performance as implemented in the R loop. The trace plots demonstrate that the Markov chains for all four parameters were initialized at 0 and rapidly converged toward their true underlying values (indicated by the red dashed lines). This near-instantaneous burn-in, stabilizing well before the 1,000-iteration cutoff (black dotted line), highlights the computational efficiency of the exact Pólya-Gamma data augmentation technique compared to heavily autocorrelated Metropolis-Hastings random walks. Post burn-in, the chains exhibit dense, high-frequency oscillation around the target (ground truth). This visual diagnostic indicates excellent mixing and confirms that the algorithm is successfully and consistently sampling from the stationary posterior distribution.

5. Diagnostics and Inference

After sampling, we assess convergence and extract the 95% Credible Intervals for our parameters.

```r
#### Diagnostics and Inference ####
library(bayesplot)
library(ggplot2)

feature_names <- c("Intercept", "Word_Free", "Word_Urgent", "Has_Attachment")
colnames(posterior_beta) <- feature_names
mcmc_chain <- mcmc(posterior_beta)

# Parameter Recovery
summary_stats <- summary(mcmc_chain)$quantiles
results_table <- data.frame(
  True_Beta = true_beta,
  Posterior_Mean = colMeans(posterior_beta),
  Lower_95_CI = summary_stats[, 1],
  Upper_95_CI = summary_stats[, 5]
)
print(round(results_table, 3))
```

OUTPUT:

```
               True_Beta Posterior_Mean Lower_95_CI Upper_95_CI
Intercept           -1.5         -1.436      -1.663      -1.213
Word_Free            2.0          1.910       1.637       2.188
Word_Urgent          1.2          1.215       1.003       1.444
Has_Attachment      -0.8         -0.838      -1.046      -0.638
```

The summary table and Figure 2 collectively confirm that the MCMC algorithm successfully recovered the true underlying data-generating parameters, validating the mathematical accuracy of the Pólya-Gamma Gibbs sampler. As detailed in the table, the calculated posterior means closely estimate the true beta coefficients (e.g., an estimated 1.910 versus the true 2.0 for *Word_Free*), while the 95% Credible Intervals, defined by the lower and upper bounds, successfully bracket every respective true target. Figure 2 visualizes this precise parameter recovery, displaying narrow posterior density curves where the posterior means, marked by the bold vertical lines, perfectly align with the expected statistical values. The shaded blue regions representing the 95% certainty for the predictor variables do not cross zero, which provides distinct inferential confidence regarding their influence on classification. For instance, the credible interval for *Word_Free* is strictly positive at (1.637, 2.188), indicating high algorithmic certainty that the presence of this word significantly increases the probability of an email being spam, whereas the strictly negative interval for *Has_Attachment* (-1.046, -0.638) confidently establishes its inverse relationship to spam within this synthetic dataset.

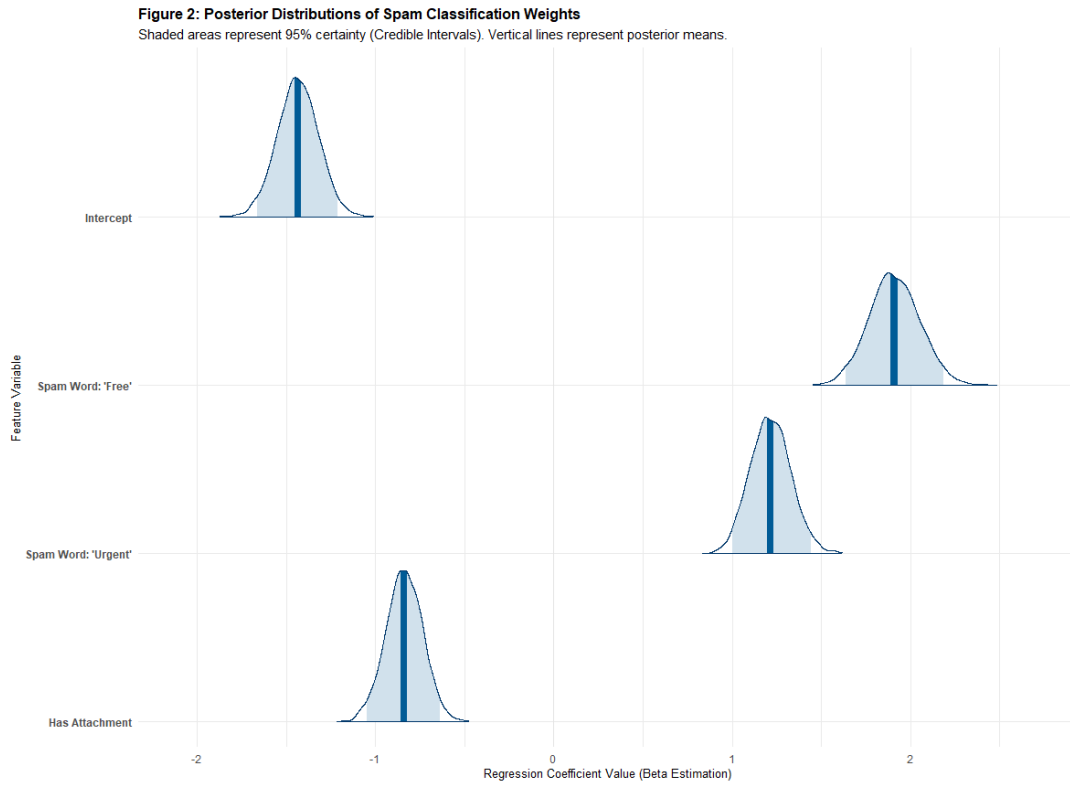

Figure 2. Posterior density plots generated by *bayesplot*, illustrating the algorithmic certainty regarding the influence of each feature.

6. Posterior Predictive Checks (Classification of New Email)

The primary advantage of Bayesian machine learning is robust uncertainty quantification during inference. When a new email arrives, we do not multiply its features by a single vector of weights. Instead, we multiply its features by the *entire matrix* of posterior samples, generating a distribution of spam probabilities.

```r
#### Posterior Predictive Checks ####
# 1. Define a new, unseen email (e.g., contains "Free" but no "Urgent" or Attachment)
x_new <- c(1, 2.5, 0, 0) # Intercept, Word_Free=2.5, Word_Urgent=0, Has_Attachment=0

# 2. Calculate the linear predictor (psi) for ALL 4000 posterior samples
psi_new <- posterior_beta %*% x_new

# 3. Transform to probability scale using the logistic function
p_new_samples <- 1 / (1 + exp(-psi_new))

# 4. Calculate predictive metrics
p_mean <- mean(p_new_samples)
p_lower <- quantile(p_new_samples, 0.025)
p_upper <- quantile(p_new_samples, 0.975)

cat("Posterior Predictive Probability of Spam:\n")
cat("Mean Probability:", round(p_mean, 3), "\n")
cat("95% CI: [", round(p_lower, 3), ",", round(p_upper, 3), "]\n")
```

OUTPUT:

```
|      |Metric              | Value |
|:-----|:------------------|:-----:|
|      |Mean Probability    | 0.976 |
|2.5%  |Lower 95% CI Bound  | 0.958 |
|97.5% |Upper 95% CI Bound  | 0.988 |
```

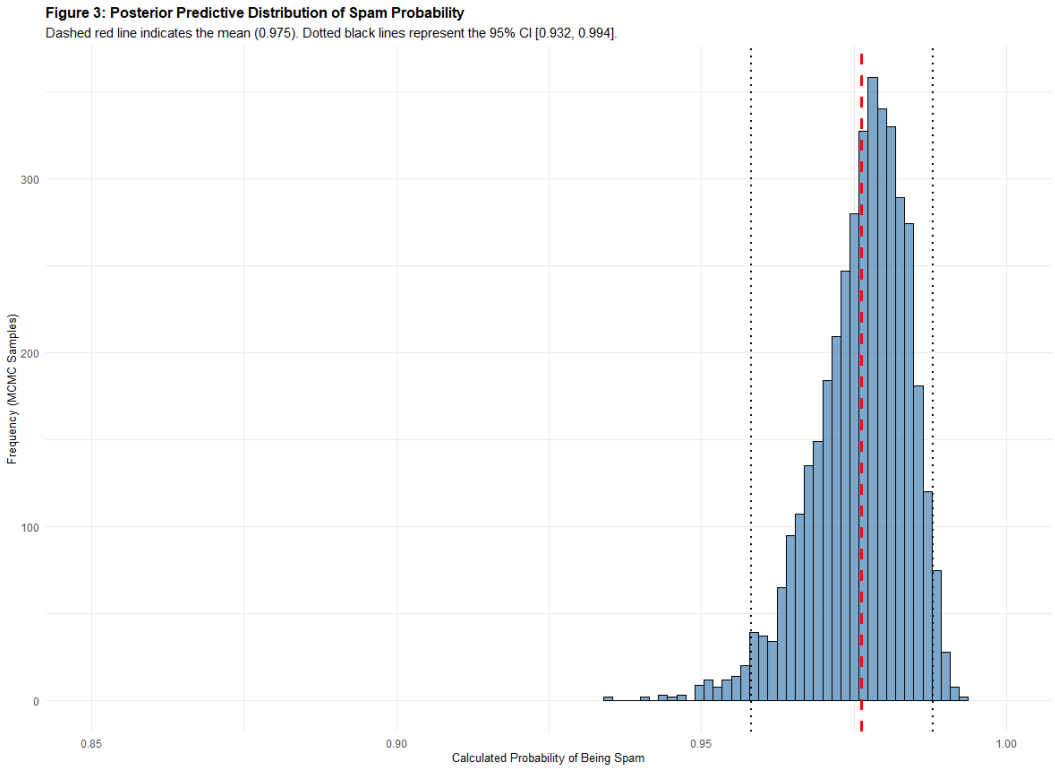

Figure 3: A histogram representing the distribution of calculated probabilities for the new email.

For the newly tested email, the Bayesian model provides a mean predictive probability of 97.6% that the message is spam. As illustrated in Figure 3, this result is a complete posterior predictive distribution derived from evaluating the new email against all post-burn-in MCMC samples. The histogram reveals a tightly clustered distribution heavily concentrated near 1.0. More importantly, it shows that the 95% Credible Interval spans from 95.8% to 98.8%. Because this entire interval is very close to 1.0 and securely above any standard classification threshold, the system can confidently route this email directly to the spam folder without human intervention and with a near-zero risk of generating a false positive. With this MCMC implementation, if a new email generates a wide 95% credible interval that spans across 0.50 decision boundary (for instance, [0.35, 0.65]), the algorithm natively exposes its statistical uncertainty. This allows production email systems to handle edge cases defensively, routing highly uncertain, borderline emails to a human review rather than permanently deleting potentially legitimate correspondence.
